CP/M 2.0 ALTERATION GUIDE

Copyright (c) 1979
Digital Research, Box 579
Pacific Grove, California

1. INTRODUCTION

The standard CP/M system assumes operation on an Intel MDS-800 microcomputer development system, but is designed so that the user can alter a specific set of subroutines which define the hardware operating environment. In this way, the user can produce a diskette which operates with any IBM-3741 format compatible drive controller and other peripheral devices.

Although standard CP/M 2.0 is configured for single density floppy disks, field-alteration features allow adaptation to a wide variety of disk subsystems from single drive minidisks through high-capacity "hard disk" systems. In order to simplify the following adaptation process, we assume that CP/M 2.0 will first be configured for single density floppy disks where minimal editing and debugging tools are available. If an earlier version of CP/M is available, the customizing process is eased considerably. In this latter case, you may wish to briefly review the system generation process, and skip to later sections which discuss system alteration for non-standard disk systems.

In order to achieve device independence, CP/M is separated into three distinct modules:

> BIOS - basic I/O system which is environment dependent
> BDOS - basic disk operating system which is not dependent
>   upon the hardware configuration
> CCP - the console command processor which uses the BDOS

Of these modules, only the BIOS is dependent upon the particular hardware. That is, the user can "patch" the distribution version of CP/M to provide a new BIOS which provides a customized interface between the remaining CP/M modules and the user's own hardware system. The purpose of this document is to provide a step-by-step procedure for patching your new BIOS into CP/M.

If CP/M is being tailored to your computer system for the first time, the new BIOS requires some relatively simple software development and testing. The standard BIOS is listed in Appendix B, and can be used as a model for the customized package. A skeletal version of the BIOS is given in Appendix C which can serve as the basis for a modified BIOS. In addition to the BIOS, the user must write a simple memory loader, called GETSYS, which brings the operating system into memory. In order to patch the new BIOS into CP/M, the user must write the reverse of GETSYS, called PUTSYS, which places an altered version of CP/M back onto the diskette. PUTSYS can be derived from GETSYS by changing the disk read commands into disk write commands. Sample skeletal GETSYS and PUTSYS programs are described in Section 3, and listed in Appendix D. In order to make the CP/M system work automatically, the user must also supply a cold start loader, similar to the one provided with CP/M (listed in Appendices A and B). A skeletal form of a cold start loader is given in Appendix E which can serve as a model for your loader.

2. FIRST LEVEL SYSTEM REGENERATION

The procedure to follow to patch the CP/M system is given below in several steps. Address references in each step are shown with a following "H" which denotes the hexadecimal radix, and are given for a 20K CP/M system. For larger CP/M systems, add a "bias" to each address which is shown with a "+b" following it, where b is equal to the memory size - 20K. Values for b in various standard memory sizes are

```
24K:        b = 24K - 20K =  4K = 1000H
32K:        b = 32K - 20K = 12K = 3000H
40K:        b = 40K - 20K = 20K = 5000H
48K:        b = 48K - 20K = 28K = 7000H
56K:        b = 56K - 20K = 36K = 9000H
62K:        b = 62K - 20K = 42K = A800H
64K:        b = 64K - 20K = 44K = B000H
```

Note: The standard distribution version of CP/M is set for operation within a 20K memory system. Therefore, you must first bring up the 20K CP/M system, and then configure it for your actual memory size (see Second Level System Generation).

(1) Review Section 4 and write a GETSYS program which reads the first two tracks of a diskette into memory. The data from the diskette must begin at location 3380H. Code GETSYS so that it starts at location 100H (base of the TPA), as shown in the first part of Appendix d.

(2) Test the GETSYS program by reading a blank diskette into memory, and check to see that the data has been read properly, and that the diskette has not been altered in any way by the GETSYS program.

(3) Run the GETSYS program using an initialized CP/M diskette to see if GETSYS loads CP/M starting at 3380H (the operating system actually starts 128 bytes later at 3400H).

(4) Review Section 4 and write the PUTSYS program which writes memory starting at 3380H back onto the first two tracks of the diskette. The PUTSYS program should be located at 200H, as shown in the second part of Appendix D.

(5) Test the PUTSYS program using a blank uninitialized diskette by writing a portion of memory to the first two tracks; clear memory and read it back using GETSYS. Test PUTSYS completely, since this program will be used to alter CP/M on disk.

(6) Study Sections 5, 6, and 7, along with the distribution version of the BIOS given in Appendix B, and write a simple version which performs a similar function for the customized environment. Use the program given in Appendix C as a model. Call this new BIOS by the name CBIOS (customized BIOS). Implement only the primitive disk operations on a single drive, and simple console input/output functions in this phase.

(7)   Test CBIOS completely to ensure that it properly performs
console character I/O and disk reads and writes. Be especially
careful to ensure that no disk write operations occur accidently
during read operations, and check that the proper track and sectors
are addressed on all reads and writes. Failure to make these checks
may cause destruction of the initialized CP/M system after it is
patched.

(8)   Referring to Figure 1 in Section 5, note that the BIOS is
placed between locations 4A00H and 4FFFH. Read the CP/M system using
GETSYS and replace the BIOS segment by the new CBIOS developed in step
(6) and tested in step (7). This replacement is done in the memory of
the machine, and will be placed on the diskette in the next step.

(9)   Use PUTSYS to place the patched memory image of CP/M onto the
first two tracks of a blank diskette for testing.

(10) Use GETSYS to bring the copied memory image from the test
diskette back into memory at 3380H, and check to ensure that it has
loaded back properly (clear memory, if possible, before the load).
Upon successful load, branch to the cold start code at location 4A00H.
The cold start routine will initialize page zero, then jump to the CCP
at location 3400H which will call the BDOS, which will call the CBIOS.
The CBIOS will be asked by the CCP to read sixteen sectors on track 2,
and if successful, CP/M will type "A>", the system prompt.

When you make it this far, you are almost on the air. If you have
trouble, use whatever debug facilities you have available to trace and
breakpoint your CBIOS.

(11) Upon completion of step (10), CP/M has prompted the console
for a command input. Test the disk write operation by typing

        SAVE 1 X.COM

(recall that all commands must be followed by a carriage return).

CP/M should respond with another prompt (after several disk accesses):

        A>

If it does not, debug your disk write functions and retry.

    (12)   Then test the directory command by typing

        DIR

CP/M should respond with

        A: X   COM

    (13)   Test the erase command by typing

        ERA X.COM

CP/M should respond with the A prompt. When you make it this far, you should have an operational system which will only require a bootstrap loader to function completely.

(14) Write a bootstrap loader which is similar to GETSYS, and place it on track 0, sector 1 using PUTSYS (again using the test diskette, not the distribution diskette). See Sections 5 and 8 for more information on the bootstrap operation.

(15) Retest the new test diskette with the bootstrap loader installed by executing steps (11), (12), and (13). Upon completion of these tests, type a control-C (control and C keys simultaneously). The system should then execute a "warm start" which reboots the system, and types the A prompt.

(16) At this point, you probably have a good version of your customized CP/M system on your test diskette. Use GETSYS to load CP/M from your test diskette. Remove the test diskette, place the distribution diskette (or a legal copy) into the drive, and use PUTSYS to replace the distribution version by your customized version. Do not make this replacement if you are unsure of your patch since this step destroys the system which was sent to you from Digital Research.

(17) Load your modified CP/M system and test it by typing

        DIR

CP/M should respond with a list of files which are provided on the initialized diskette. One such file should be the memory image for the debugger, called DDT.COM.

NOTE: from now on, it is important that you always reboot the CP/M system (ctl-C is sufficient) when the diskette is removed and replaced by another diskette, unless the new diskette is to be read only.

(18) Load and test the debugger by typing

        DDT

(see the document "CP/M Dynamic Debugging Tool (DDT)" for operating procedures. You should take the time to become familiar with DDT, it will be your best friend in later steps.

(19) Before making further CBIOS modifications, practice using the editor (see the ED user's guide), and assembler (see the ASM user's guide). Then recode and test the GETSYS, PUTSYS, and CBIOS programs using ED, ASM, and DDT. Code and test a COPY program which does a sector-to-sector copy from one diskette to another to obtain back-up copies of the original diskette (NOTE: read your CP/M Licensing Agreement; it specifies your legal responsibilities when copying the CP/M system). Place the copyright notice

on each copy which is made with your COPY program.

(20) Modify your CBIOS to include the extra functions for punches, readers, signon messages, and so-forth, and add the facilities for a additional disk drives, if desired. You can make these changes with the GETSYS and PUTSYS programs which you have developed, or you can refer to the following section, which outlines CP/M facilities which will aid you in the regeneration process.

You now have a good copy of the customized CP/M system. Note that although the CBIOS portion of CP/M which you have developed belongs to you, the modified version of CP/M which you have created can be copied for your use only (again, read your Licensing Agreement), and cannot be legally copied for anyone else's use.

It should be noted that your system remains file-compatible with all other CP/M systems, (assuming media compatiblity, of course) which allows transfer of non-proprietary software between users of CP/M.

3. SECOND LEVEL SYSTEM GENERATION

Now that you have the CP/M system running, you will want to configure CP/M for your memory size. In general, you will first get a memory image of CP/M with the "MOVCPM" program (system relocator) and place this memory image into a named disk file. The disk file can then be loaded, examined, patched, and replaced using the debugger, and system generation program. For further details on the operation of these programs, see the "Guide to CP/M Features and Facilities" manual.

Your CBIOS and BOOT can be modified using ED, and assembled using ASM, producing files called CBIOS.HEX and BOOT.HEX, which contain the machine code for CBIOS and BOOT in Intel hex format.

To get the memory image of CP/M into the TPA configured for the desired memory size, give the command:

        MOVCPM xx *

where "xx" is the memory size in decimal K bytes (e.g., 32 for 32K). The response will be:

        CONSTRUCTING xxK CP/M VERS 2.0
        READY FOR "SYSGEN" OR
        "SAVE 34 CPMxx.COM"

At this point, an image of a CP/M in the TPA configured for the requested memory size. The memory image is at location 0900H through 227FH. (i.e., The BOOT is at 0900H, the CCP is at 980H, the BDOS starts at 1180H, and the BIOS is at 1F80H.) Note that the memory image has the standard MDS-800 BIOS and BOOT on it. It is now necessary to save the memory image in a file so that you can patch your CBIOS and CBOOT into it:

        SAVE 34 CPMxx.COM

The memory image created by the "MOVCPM" program is offset by a negative bias so that it loads into the free area of the TPA, and thus does not interfere with the operation of CP/M in higher memory. This memory image can be subsequently loaded under DDT and examined or changed in preparation for a new generation of the system. DDT is loaded with the memory image by typing:

        DDT CPMxx.COM   Load DDT, then read the CPM
                                         image

DDT should respond with

        NEXT   PC
        2300   0100
        -                                (The DDT prompt)

You can then use the display and disassembly commands to examine

portions of the memory image between 900H and 227FH. Note, however, that to find any particular address within the memory image, you must apply the negative bias to the CP/M address to find the actual address. Track 00, sector 01 is loaded to location 900H (you should find the cold start loader at 900H to 97FH), track 00, sector 02 is loaded into 980H (this is the base of the CCP), and so-forth through the entire CP/M system load. In a 20K system, for example, the CCP resides at the CP/M address 3400H, but is placed into memory at 980H by the SYSGEN program. Thus, the negative bias, denoted by n, satisfies

$$3400H + n = 980H, \text{ or } n = 980H - 3400H$$

Assuming two's complement arithmetic, n = D580H, which can be checked by

$$3400H + D580H = 10980H = 0980H \text{ (ignoring high-order}$$
$$\text{overflow)}.$$

Note that for larger systems, n satisfies

$$(3400H+b) + n = 980H, \text{ or}$$
$$n = 980H - (3400H + b), \text{ or}$$
$$n = D580H - b.$$

The value of n for common CP/M systems is given below

memory size	bias b	negative offset n		
20K	0000H	D580H −	0000H	= D580H
24K	1000H	D580H −	1000H	= C580H
32K	3000H	D580H −	3000H	= A580H
40K	5000H	D580H −	5000H	= 8580H
48K	7000H	D580H −	7000H	= 6580H
56K	9000H	D580H −	9000H	= 4580H
62K	A800H	D580H −	A800H	= 2D80H
64K	B000H	D580H −	B000H	= 2580H

Assume, for example, that you want to locate the address x within the memory image loaded under DDT in a 20K system. First type

        Hx,n   Hexadecimal sum and difference

and DDT will respond with the value of x+n (sum) and x-n (difference). The first number printed by DDT will be the actual memory address in the image where the data or code will be found. The input

        H3400,D580

for example, will produce 980H as the sum, which is where the CCP is located in the memory image under DDT.

    Use the L command to disassemble portions the BIOS located at (4A00H+b)-n   which, when you use the H command, produces an actual address of 1F80H. The disassembly command would thus be

L1F80

It is now necessary to patch in your CBOOT and CBIOS routines. The
BOOT resides at location 0900H in the memory image. If the actual
load address is "n", then to calculate the bias (m) use the command:

            H900,n   Subtract load address from
                                    target address.

The second number typed in response to the command is the desired bias
(m). For example, if your BOOT executes at 0080H, the command:

            H900,80

will reply

            0980 0880   Sum and difference in hex.

Therefore, the bias "m" would be 0880H. To read-in the BOOT, give the
command:

            ICBOOT.HEX   Input file CBOOT.HEX

Then:

            Rm   Read CBOOT with a bias of
                                    m (=900H-n)

You may now examine your CBOOT with:

            L900

We are now ready to replace the CBIOS. Examine the area at 1F80H
where the original version of the CBIOS resides. Then type

            ICBIOS.HEX   Ready the "hex" file for loading

assume that your CBIOS is being integrated into a 20K CP/M system, and
thus is origined at location 4A00H. In order to properly locate the
CBIOS in the memory image under DDT, we must apply the negative bias n
for a 20K system when loading the hex file. This is accomplished by
typing

            RD580   Read the file with bias D580H

Upon completion of the read, re-examine the area where the CBIOS has
been loaded (use an "L1F80" command), to ensure that is was loaded
properly. When you are satisfied that the change has been made,
return from DDT using a control-C or "G0" command.

     Now use SYSGEN to replace the patched memory image back onto a
diskette (use a test diskette until you are sure of your patch), as
shown in the following interaction

```
SYSGEN                       Start the SYSGEN program
SYSGEN VERSION 2.0           Sign-on message from SYSGEN
SOURCE DRIVE NAME (OR RETURN TO SKIP)
                             Respond with a carriage return
                             to skip the CP/M read operation
                             since the system is already in
                             memory.
DESTINATION DRIVE NAME (OR RETURN TO REBOOT)
                             Respond with "B" to write the
                             new system to the diskette in
                             drive B.
DESTINATION ON B, THEN TYPE RETURN
                             Place a scratch diskette in
                             drive B, then type return.
FUNCTION COMPLETE
DESTINATION DRIVE NAME (OR RETURN TO REBOOT)
```

Place the scratch diskette in your drive A, and then perform a
coldstart to bring up the new CP/M system you have configured.

Test the new CP/M system, and place the Digital Research copyright
notice on the diskette, as specified in your Licensing Agreement:

4. SAMPLE GETSYS AND PUTSYS PROGRAMS

The following program provides a framework for the GETSYS and PUTSYS programs referenced in Section 2. The READSEC and WRITESEC subroutines must be inserted by the user to read and write the specific sectors.

```
        ;    GETSYS PROGRAM - READ TRACKS 0 AND 1 TO MEMORY AT 3380H
        ;    REGISTER                USE
        ;       A             (SCRATCH REGISTER)
        ;       B             TRACK COUNT (0, 1)
        ;       C             SECTOR COUNT (1,2,...,26)
        ;       DE            (SCRATCH REGISTER PAIR)
        ;       HL            LOAD ADDRESS
        ;       SP            SET TO STACK ADDRESS
        ;
START:  LXI    SP,3380H     ;SET STACK POINTER TO SCRATCH AREA
        LXI    H, 3380H     ;SET BASE LOAD ADDRESS
        MVI    B, 0         ;START WITH TRACK 0
RDTRK:                      ;READ NEXT TRACK (INITIALLY 0)
        MVI    C,1          ;READ STARTING WITH SECTOR 1
RDSEC:                      ;READ NEXT SECTOR
        CALL   READSEC      ;USER-SUPPLIED SUBROUTINE
        LXI    D,128        ;MOVE LOAD ADDRESS TO NEXT 1/2 PAGE
        DAD    D            ;HL = HL + 128
        INR    C            ;SECTOR = SECTOR + 1
        MOV    A,C          ;CHECK FOR END OF TRACK
        CPI    27
        JC     RDSEC        ;CARRY GENERATED IF SECTOR < 27
        ;
        ;   ARRIVE HERE AT END OF TRACK, MOVE TO NEXT TRACK
        INR    B
        MOV    A,B          ;TEST FOR LAST TRACK
        CPI    2
        JC     RDTRK        ;CARRY GENERATED IF TRACK < 2
        ;
        ;   ARRIVE HERE AT END OF LOAD, HALT FOR NOW
        HLT
        ;
        ;   USER-SUPPLIED SUBROUTINE TO READ THE DISK
READSEC:
        ;   ENTER WITH TRACK NUMBER IN REGISTER B,
        ;       SECTOR NUMBER IN REGISTER C, AND
        ;       ADDRESS TO FILL IN HL
        ;
        PUSH   B            ;SAVE B AND C REGISTERS
        PUSH   H            ;SAVE HL REGISTERS
        ...........................................
        perform disk read at this point, branch to

        label START if an error occurs
        ...........................................
        POP    H            ;RECOVER HL
        POP    B            ;RECOVER B AND C REGISTERS
        RET                 ;BACK TO MAIN PROGRAM

        END    START
```

Note that this program is assembled and listed in Appendix C for reference purposes, with an assumed origin of 100H. The hexadecimal operation codes which are listed on the left may be useful if the program has to be entered through your machine's front panel switches.

The PUTSYS program can be constructed from GETSYS by changing only a few operations in the GETSYS program given above, as shown in Appendix D. The register pair HL become the dump address (next address to write), and operations upon these registers do not change within the program. The READSEC subroutine is replaced by a WRITESEC subroutine which performs the opposite function: data from address HL is written to the track given by register B and sector given by register C. It is often useful to combine GETSYS and PUTSYS into a single program during the test and development phase, as shown in the Appendix.

5. DISKETTE ORGANIZATION

The sector allocation for the standard distribution version of CP/M is given here for reference purposes. The first sector (see table on the following page) contains an optional software boot section. Disk controllers are often set up to bring track 0, sector 1 into memory at a specific location (often location 0000H). The program in this sector, called BOOT, has the responsibility of bringing the remaining sectors into memory starting at location 3400H+b. If your controller does not have a built-in sector load, you can ignore the program in track 0, sector 1, and begin the load from track 0 sector 2 to location 3400H+b.

As an example, the Intel MDS-800 hardware cold start loader brings track 0, sector 1 into absolute address 3000H. Upon loading this sector, control transfers to location 3000H, where the bootstrap operation commences by loading the remainder of tracks 0, and all of track 1 into memory, starting at 3400H+b. The user should note that this bootstrap loader is of little use in a non-MDS environment, although it is useful to examine it since some of the boot actions will have to be duplicated in your cold start loader.

Track#	Sector#	Page#	Memory Address	CP/M Module name
00	01		(boot address)	Cold Start Loader
00	02	00	3400H+b	CCP

6. THE BIOS ENTRY POINTS

The entry points into the BIOS from the cold start loader and BDOS are detailed below. Entry to the BIOS is through a "jump vector" located at 4A00H+b, as shown below (see Appendices B and C, as well). The jump vector is a sequence of 17 jump instructions which send program control to the individual BIOS subroutines. The BIOS subroutines may be empty for certain functions (i.e., they may contain a single RET operation) during regeneration of CP/M, but the entries must be present in the jump vector.

The jump vector at 4A00H+b takes the form shown below, where the individual jump addresses are given to the left:

```
4A00H+b      JMP BOOT        ; ARRIVE HERE FROM COLD START LOAD
4A03H+b      JMP WBOOT       ; ARRIVE HERE FOR WARM START
4A06H+b      JMP CONST       ; CHECK FOR CONSOLE CHAR READY
4A09H+b      JMP CONIN       ; READ CONSOLE CHARACTER IN
4A0CH+b      JMP CONOUT      ; WRITE CONSOLE CHARACTER OUT
4A0FH+b      JMP LIST        ; WRITE LISTING CHARACTER OUT
4A12H+b      JMP PUNCH       ; WRITE CHARACTER TO PUNCH DEVICE
4A15H+b      JMP READER      ; READ READER DEVICE
4A18H+b      JMP HOME        ; MOVE TO TRACK 00 ON SELECTED DISK
4A1BH+b      JMP SELDSK      ; SELECT DISK DRIVE
4A1EH+b      JMP SETTRK      ; SET TRACK NUMBER
4A21H+b      JMP SETSEC      ; SET SECTOR NUMBER
4A24H+b      JMP SETDMA      ; SET DMA ADDRESS
4A27H+b      JMP READ        ; READ SELECTED SECTOR
4A2AH+b      JMP WRITE       ; WRITE SELECTED SECTOR
4A2DH+b      JMP LISTST      ; RETURN LIST STATUS
4A30H+b      JMP SECTRAN     ; SECTOR TRANSLATE SUBROUTINE
```

Each jump address corresponds to a particular subroutine which performs the specific function, as outlined below. There are three major divisions in the jump table: the system (re)initialization which results from calls on BOOT and WBOOT, simple character I/O performed by calls on CONST, CONIN, CONOUT, LIST, PUNCH, READER, and LISTST, and diskette I/O performed by calls on HOME, SELDSK, SETTRK, SETSEC, SETDMA, READ, WRITE, and SECTRAN.

All simple character I/O operations are assumed to be performed in ASCII, upper and lower case, with high order (parity bit) set to zero. An end-of-file condition for an input device is given by an ASCII control-z (1AH). Peripheral devices are seen by CP/M as "logical" devices, and are assigned to physical devices within the BIOS.

In order to operate, the BDOS needs only the CONST, CONIN, and CONOUT subroutines (LIST, PUNCH, and READER may be used by PIP, but not the BDOS). Further, the LISTST entry is used currently only by DESPOOL, and thus, the initial version of CBIOS may have empty subroutines for the remaining ASCII devices.

The characteristics of each device are

CONSOLE   The principal interactive console which communicates
           with the operator, accessed through CONST, CONIN, and
           CONOUT. Typically, the CONSOLE is a device such as a
           CRT or Teletype.

LIST   The principal listing device, if it exists on your
           system, which is usually a hard-copy device, such as a
           printer or Teletype.

PUNCH   The principal tape punching device, if it exists, which
           is normally a high-speed paper tape punch or Teletype.

READER   The principal tape reading device, such as a simple
           optical reader or Teletype.

           Note that a single peripheral can be assigned as
the LIST, PUNCH, and READER device simultaneously. If
no peripheral device is assigned as the LIST, PUNCH, or
READER device, the CBIOS created by the user may give
an appropriate error message so that the system does
not "hang" if the device is accessed by PIP or some
other user program. Alternately, the PUNCH and LIST
routines can just simply return, and the READER routine
can return with a 1AH (ctl-Z) in reg A to indicate
immediate end-of-file.

           For added flexibility, the user can optionally
implement the "IOBYTE" function which allows
reassignment of physical and logical devices. The
IOBYTE function creates a mapping of logical to
physical devices which can be altered during CP/M
processing (see the STAT command). The definition of
the IOBYTE function corresponds to the Intel standard
as follows: a single location in memory (currently
location 0003H) is maintained, called IOBYTE, which
defines the logical to physical device mapping which is
in effect at a particular time. The mapping is
performed by splitting the IOBYTE into four distinct
fields of two bits each, called the CONSOLE, READER,
PUNCH, and LIST fields, as shown below:

```
                most significant        least significant
               ---------------------------------------------
IOBYTE AT 0003H | LIST    | PUNCH   | READER  | CONSOLE |
               ---------------------------------------------
                bits 6,7  bits 4,5  bits 2,3  bits 0,1
```

           The value in each field can be in the range 0-3,
defining the assigned source or destination of each
logical device. The values which can be assigned to
each field are given below

CONSOLE field (bits 0,1)
    0 - console is assigned to the console printer device (TTY:)
    1 - console is assigned to the CRT device (CRT:)
    2 - batch mode: use the READER as the CONSOLE input,
         and the LIST device as the CONSOLE output (BAT:)
    3 - user defined console device (UC1:)

READER field (bits 2,3)
    0 - READER is the Teletype device (TTY:)
    1 - READER is the high-speed reader device (RDR:)
    2 - user defined reader # 1 (UR1:)
    3 - user defined reader # 2 (UR2:)

PUNCH field (bits 4,5)
    0 - PUNCH is the Teletype device (TTY:)
    1 - PUNCH is the high speed punch device (PUN:)
    2 - user defined punch # 1 (UP1:)
    3 - user defined punch # 2 (UP2:)

LIST field (bits 6,7)
    0 - LIST is the Teletype device (TTY:)
    1 - LIST is the CRT device (CRT:)
    2 - LIST is the line printer device (LPT:)
    3 - user defined list device (UL1:)

Note again that the implementation of the IOBYTE is optional, and affects only the organization of your CBIOS. No CP/M systems use the IOBYTE (although they tolerate the existence of the IOBYTE at location 0003H), except for PIP which allows access to the physical devices, and STAT which allows logical-physical assignments to be made and/or displayed (for more information, see the "CP/M Features and Facilities Guide"). In any case, the IOBYTE implementation should be omitted until your basic CBIOS is fully implemented and tested; then add the IOBYTE to increase your facilities.

Disk I/O is always performed through a sequence of calls on the various disk access subroutines which set up the disk number to access, the track and sector on a particular disk, and the direct memory access (DMA) address involved in the I/O operation. After all these parameters have been set up, a call is made to the READ or WRITE function to perform the actual I/O operation. Note that there is often a single call to SELDSK to select a disk drive, followed by a number of read or write operations to the selected disk before selecting another drive for subsequent operations. Similarly, there may be a single call to set the DMA address, followed by several calls which read or write from the selected DMA address before the DMA address is changed. The track and sector subroutines are always called before the READ or WRITE operations are performed.

Note that the READ and WRITE routines should perform several retries (10 is standard) before reporting the error condition to the BDOS. If the error condition is returned to the BDOS, it will report the error to the user. The HOME subroutine may or may not actually perform the track 00 seek, depending upon your controller characteristics; the important point is that track 00 has been selected for the next operation, and is often treated in exactly the same manner as SETTRK with a parameter of 00.

The exact responsibilites of each entry point subroutine are given below:

BOOT   The BOOT entry point gets control from the cold start loader and is responsible for basic system initialization, including sending a signon message (which can be omitted in the first version). If the IOBYTE function is implemented, it must be set at this point. The various system parameters which are set by the WBOOT entry point must be initialized, and control is transferred to the CCP at 3400H+b for further processing. Note that reg C must be set to zero to select drive A.

WBOOT   The WBOOT entry point gets control when a warm start occurs. A warm start is performed whenever a user program branches to location 0000H, or when the CPU is reset from the front panel. The CP/M system must be loaded from the first two tracks of drive A up to, but not including, the BIOS (or CBIOS, if you have completed your patch). System parameters must be initialized as shown below:

            location 0,1,2   set to JMP WBOOT for warm starts
                              (0000H: JMP 4A03H+b)
            location 3   set initial value of IOBYTE, if
                              implemented in your CBIOS
            location 5,6,7   set to JMP BDOS, which is the
                              primary entry point to CP/M for
                              transient programs. (0005H: JMP
                              3C06H+b)

        (see Section 9 for complete details of page zero use) Upon completion of the initialization, the WBOOT program must branch to the CCP at 3400H+b to (re)start the system. Upon entry to the CCP, register C is set to the drive to select after system initialization.

CONST   Sample the status of the currently assigned console device and return 0FFH in register A if a character is ready to read, and 00H in register A if no console characters are ready.

CONIN   Read the next console character into register A, and

set the parity bit (high order bit) to zero. If no console character is ready, wait until a character is typed before returning.

CONOUT
Send the character from register C to the console output device. The character is in ASCII, with high order parity bit set to zero. You may want to include a time-out on a line feed or carriage return, if your console device requires some time interval at the end of the line (such as a TI Silent 700 terminal). You can, if you wish, filter out control characters which cause your console device to react in a strange way (a control-z causes the Lear Seigler terminal to clear the screen, for example).

LIST
Send the character from register C to the currently assigned listing device. The character is in ASCII with zero parity.

PUNCH
Send the character from register C to the currently assigned punch device. The character is in ASCII with zero parity.

READER
Read the next character from the currently assigned reader device into register A with zero parity (high order bit must be zero), an end of file condition is reported by returning an ASCII control-z (1AH).

HOME
Return the disk head of the currently selected disk (initially disk A) to the track 00 position. If your controller allows access to the track 0 flag from the drive, step the head until the track 0 flag is detected. If your controller does not support this feature, you can translate the HOME call into a call on SETTRK with a parameter of 0.

SELDSK
Select the disk drive given by register C for further operations, where register C contains 0 for drive A, 1 for drive B, and so-forth up to 15 for drive P (the standard CP/M distribution version supports four drives). On each disk select, SELDSK must return in HL the base address of a 16-byte area, called the Disk Parameter Header, described in the Section 10. For standard floppy disk drives, the contents of the header and associated tables does not change, and thus the program segment included in the sample CBIOS performs this operation automatically. If there is an attempt to select a non-existent drive, SELDSK returns HL=0000H as an error indicator. Although SELDSK must return the header address on each call, it is advisable to postpone the actual physical disk select operation until an I/O function (seek, read or write) is actually performed, since disk selects often occur without utimately performing any disk I/O, and many controllers will unload the head of the current disk

SETTRK   Register BC contains the track number for subsequent
          disk accesses on the currently selected drive. You
          can choose to seek the selected track at this time, or
          delay the seek until the next read or write actually
          occurs.   Register BC can take on values in the range
          0-76 corresponding to valid track numbers for standard
          floppy disk drives, and 0-65535 for non-standard disk
          subsystems.

SETSEC   Register BC contains the sector number (1 through 26)
          for subsequent disk accesses on the currently selected
          drive. You can choose to send this information to the
          controller at this point, or instead delay sector
          selection until a read or write operation occurs.

SETDMA   Register BC contains the DMA (disk memory access)
          address for subsequent read or write operations. For
          example, if B = 00H and C = 80H when SETDMA is called,
          then all subsequent read operations read their data
          into 80H through 0FFH, and all subsequent write
          operations get their data from 80H through 0FFH, until
          the next call to SETDMA occurs. The initial DMA
          address is assumed to be 80H. Note that the
          controller need not actually support direct memory
          access. If, for example, all data is received and
          sent through I/O ports, the CBIOS which you construct
          will use the 128 byte area starting at the selected
          DMA address for the memory buffer during the following
          read or write operations.

READ   Assuming the drive has been selected, the track has
          been set, the sector has been set, and the DMA address
          has been specified, the READ subroutine attempts to
          read one sector based upon these parameters, and
          returns the following error codes in register A:

          0   no errors occurred
          1   non-recoverable error condition occurred

          Currently, CP/M responds only to a zero or non-zero
          value as the return code. That is, if the value in
          register A is 0 then CP/M assumes that the disk
          operation completed properly. If an error occurs,
          however, the CBIOS should attempt at least 10 retries
          to see if the error is recoverable. When an error is
          reported the BDOS will print the message "BDOS ERR ON
          x: BAD SECTOR". The operator then has the option of
          typing <cr> to ignore the error, or ctl-C to abort.

WRITE   Write the data from the currently selected DMA address
          to the currently selected drive, track, and sector.
          The data should be marked as "non deleted data" to

(All Information Contained Herein is Proprietary to Digital Research.)

19

maintain compatibility with other CP/M systems. The error codes given in the READ command are returned in register A, with error recovery attempts as described above.

LISTST   Return the ready status of the list device. Used by the DESPOOL program to improve console response during its operation. The value 00 is returned in A if the list device is not ready to accept a character, and 0FFH if a character can be sent to the printer. Note that a 00 value always suffices.

SECTRAN   Performs sector logical to physical sector translation in order to improve the overall response of CP/M. Standard CP/M systems are shipped with a "skew factor" of 6, where six physical sectors are skipped between each logical read operation. This skew factor allows enough time between sectors for most programs to load their buffers without missing the next sector. In particular computer systems which use fast processors, memory, and disk subsystems, the skew factor may be changed to improve overall response. Note, however, that you should maintain a single density IBM compatible version of CP/M for information transfer into and out of your computer system, using a skew factor of 6. In general, SECTRAN receives a logical sector number in BC, and a translate table address in DE. The sector number is used as an index into the translate table, with the resulting physical sector number in HL. For standard systems, the tables and indexing code is provided in the CBIOS and need not be changed.

7. A SAMPLE BIOS

The program shown in Appendix C can serve as a basis for your first BIOS. The simplest functions are assumed in this BIOS, so that you can enter it through the front panel, if absolutely necessary. Note that the user must alter and insert code into the subroutines for CONST, CONIN, CONOUT, READ, WRITE, and WAITIO subroutines. Storage is reserved for user-supplied code in these regions. The scratch area reserved in page zero (see Section 9) for the BIOS is used in this program, so that it could be implemented in ROM, if desired.

Once operational, this skeletal version can be enhanced to print the initial sign-on message and perform better error recovery. The subroutines for LIST, PUNCH, and READER can be filled-out, and the IOBYTE function can be implemented.

8. A SAMPLE COLD START LOADER

The program shown in Appendix D can serve as a basis for your cold start loader. The disk read function must be supplied by the user, and the program must be loaded somehow starting at location 0000. Note that space is reserved for your patch so that the total amount of storage required for the cold start loader is 128 bytes. Eventually, you will probably want to get this loader onto the first disk sector (track 0, sector 1), and cause your controller to load it into memory automatically upon system start-up. Alternatively, you may wish to place the cold start loader into ROM, and place it above the CP/M system. In this case, it will be necessary to originate the program at a higher address, and key-in a jump instruction at system start-up which branches to the loader. Subsequent warm starts will not require this key-in operation, since the entry point 'WBOOT' gets control, thus bringing the system in from disk automatically. Note also that the skeletal cold start loader has minimal error recovery, which may be enhanced on later versions.

9. RESERVED LOCATIONS IN PAGE ZERO

Main memory page zero, between locations 00H and 0FFH, contains several segments of code and data which are used during CP/M processing. The code and data areas are given below for reference purposes.

Locations from to	Contents
0000H - 0002H	Contains a jump instruction to the warm start entry point at location 4A03H+b. This allows a simple programmed restart (JMP 0000H) or manual restart from the front panel.
0003H - 0003H	Contains the Intel standard IOBYTE, which is optionally included in the user's CBIOS, as described in Section 6.
0004H - 0004H	Current default drive number (0=A,...,15=P).
0005H - 0007H	Contains a jump instruction to the BDOS,and serves two purposes: JMP 0005H provides the primary entry point to the BDOS, as described in the manual "CP/M Interface Guide," and LHLD 0006H brings the address field of the instruction to the HL register pair. This value is the lowest address in memory used by CP/M (assuming the CCP is being overlayed). Note that the DDT program will change the address field to reflect the reduced memory size in debug mode.
0008H - 0027H	(interrupt locations 1 through 5 not used)
0030H - 0037H	(interrupt location 6, not currently used - reserved)
0038H - 003AH	Restart 7 - Contains a jump instruction into the DDT or SID program when running in debug mode for programmed breakpoints, but is not otherwise used by CP/M.
003BH - 003FH	(not currently used - reserved)
0040H - 004FH	16 byte area reserved for scratch by CBIOS, but is not used for any purpose in the distribution version of CP/M
0050H - 005BH	(not currently used - reserved)
005CH - 007CH	default file control block produced for a transient program by the Console Command Processor.
007DH - 007FH	Optional default random record position

0080H - 00FFH   default 128 byte disk buffer (also filled with
                       the command line when a transient is loaded
                       under the CCP).

     Note that this information is set-up for normal operation under
the CP/M system, but can be overwritten by a transient program if the
BDOS facilities are not required by the transient.

     If, for example, a particular program performs only simple I/O and
must begin execution at location 0, it can be first loaded into the
TPA, using normal CP/M facilities, with a small memory move program
which gets control when loaded (the memory move program must get
control from location 0100H, which is the assumed beginning of all
transient programs). The move program can then proceed to move the
entire memory image down to location 0, and pass control to the
starting address of the memory load.   Note that if the BIOS is
overwritten, or if location 0 (containing the warm start entry point)
is overwritten, then the programmer must bring the CP/M system back
into memory with a cold start sequence.

10. DISK PARAMETER TABLES.

Tables are included in the BIOS which describe the particular characteristics of the disk subsystem used with CP/M. These tables can be either hand-coded, as shown in the sample CBIOS in Appendix C, or automatically generated using the DISKDEF macro library, as shown in Appendix B. The purpose here is to describe the elements of these tables.

In general, each disk drive has an associated (16-byte) disk parameter header which both contains information about the disk drive and provides a scratchpad area for certain BDOS operations. The format of the disk parameter header for each drive is shown below

```
                Disk     Parameter    Header
     ----------------------------------------------------------------
     |  XLT  | 0000 | 0000 | 0000 |DIRBUF|  DPB  |  CSV  |  ALV  |
     ----------------------------------------------------------------
       16b     16b    16b    16b    16b    16b     16b     16b
```

where each element is a word (16-bit) value. The meaning of each Disk Parameter Header (DPH) element is

XLT
: Address of the logical to physical translation vector, if used for this particular drive, or the value 0000H if no sector translation takes place (i.e, the physical and logical sector numbers are the same). Disk drives with identical sector skew factors share the same translate tables.

0000
: Scratchpad values for use within the BDOS (initial value is unimportant).

DIRBUF
: Address of a 128 byte scratchpad area for directory operations within BDOS. All DPH's address the same scratchpad area.

DPB
: Address of a disk parameter block for this drive. Drives with identical disk characteristics address the same disk parameter block.

CSV
: Address of a scratchpad area used for software check for changed disks. This address is different for each DPH.

ALV
: Address of a scratchpad area used by the BDOS to keep disk storage allocation information. This address is different for each DPH.

Given n disk drives, the DPH's are arranged in a table whose first row of 16 bytes corresponds to drive 0, with the last row corresponding to drive n-1. The table thus appears as

```
DPBASE:
    --------------------------------------------------------------
00 |XLT 00| 0000 | 0000 | 0000 |DIRBUF|DBP 00|CSV 00|ALV 00|
    --------------------------------------------------------------
01 |XLT 01| 0000 | 0000 | 0000 |DIRBUF|DBP 01|CSV 01|ALV 01|
    --------------------------------------------------------------
                    (and so-forth through)
    --------------------------------------------------------------
n-1|XLTn-1| 0000 | 0000 | 0000 |DIRBUF|DBPn-1|CSVn-1|ALVn-1|
    --------------------------------------------------------------
```

where the label DPBASE defines the base address of the DPH table.

A responsibility of the SELDSK subroutine is to return the base address of the DPH for the selected drive. The following sequence of operations returns the table address, with a 0000H returned if the selected drive does not exist.

```
NDISKS      EQU     4    ;NUMBER OF DISK DRIVES
......
SELDSK:
            ;SELECT DISK GIVEN BY BC
            LXI     H,0000H   ;ERROR CODE
            MOV     A,C       ;DRIVE OK?
            CPI     NDISKS    ;CY IF SO
            RNC               ;RET IF ERROR
            ;NO ERROR, CONTINUE
            MOV     L,C       ;LOW(DISK)
            MOV     H,B       ;HIGH(DISK)
            DAD     H         ;*2
            DAD     H         ;*4
            DAD     H         ;*8
            DAD     H         ;*16
            LXI     D,DPBASE  ;FIRST DPH
            DAD     D         ;DPH(DISK)
            RET
```

The translation vectors (XLT 00 through XLTn-1) are located elsewhere in the BIOS, and simply correspond one-for-one with the logical sector numbers zero through the sector count-1. The Disk Parameter Block (DPB) for each drive is more complex. A particular DPB, which is addressed by one or more DPH's, takes the general form

SPT	BSH	BLM	EXM	DSM	DRM	AL0	AL1	CKS	OFF
16b	8b	8b	8b	16b	16b	8b	8b	16b	16b

where each is a byte or word value, as shown by the "8b" or "16b" indicator below the field.

SPT   is the total number of sectors per track

BSH   is the data allocation block shift factor, determined by the data block allocation size.

EXM   is the extent mask, determined by the data block
           allocation size and the number of disk blocks.

DSM   determines the total storage capacity of the disk drive

DRM   determines the total number of directory entries which
           can be stored on this drive AL0,AL1 determine reserved
           directory blocks.

CKS   is the size of the directory check vector

OFF   is the number of reserved tracks at the beginning of
           the (logical) disk.

The values of BSH and BLM determine (implicitly) the data allocation
size BLS, which is not an entry in the disk parameter block. Given
that the designer has selected a value for BLS, the values of BSH and
BLM are shown in the table below

BLS	BSH	BLM
1,024	3	7
2,048	4	15
4,096	5	31
8,192	6	63
16,384	7	127

where all values are in decimal. The value of EXM depends upon both
the BLS and whether the DSM value is less than 256 or greater than
255, as shown in the following table

BLS	DSM < 256	DSM > 255
1,024	0	N/A
2,048	1	0
4,096	3	1
8,192	7	3
16,384	15	7

The value of DSM is the maximum data block number supported by
this particular drive, measured in BLS units. The product BLS times
(DSM+1) is the total number of bytes held by the drive and, of course,
must be within the capacity of the physical disk, not counting the
reserved operating system tracks.

The DRM entry is the one less than the total number of directory
entries, which can take on a 16-bit value. The values of AL0 and AL1,
however, are determined by DRM. The two values AL0 and AL1 can
together be considered a string of 16-bits, as shown below.

```
 ---------------------------------------------------------
|              AL0             |             AL1          |
 ---------------------------------------------------------
| | | | | | | | | | | | | | | | | | | | | | | | | | | | |
 ---------------------------------------------------------
  00 01 02 03 04 05 06 07 08 09 10 11 12 13 14 15
```

where position 00 corresponds to the high order bit of the byte labelled AL0, and 15 corresponds to the low order bit of the byte labelled AL1. Each bit position reserves a data block for number of directory entries, thus allowing a total of 16 data blocks to be assigned for directory entries (bits are assigned starting at 00 and filled to the right until position 15). Each directory entry occupies 32 bytes, resulting in the following table

BLS	Directory Entries
1,024	32 times # bits
2,048	64 times # bits
4,096	128 times # bits
8,192	256 times # bits
16,384	512 times # bits

Thus, if DRM = 127 (128 directory entries), and BLS = 1024, then there are 32 directory entries per block, requiring 4 reserved blocks. In this case, the 4 high order bits of AL0 are set, resulting in the values AL0 = 0F0H and AL1 = 00H.

The CKS value is determined as follows: if the disk drive media is removable, then CKS = (DRM+1)/4, where DRM is the last directory entry number. If the media is fixed, then set CKS = 0 (no directory records are checked in this case).

Finally, the OFF field determines the number of tracks which are skipped at the beginning of the physical disk. This value is automatically added whenever SETTRK is called, and can be used as a mechanism for skipping reserved operating system tracks, or for partitioning a large disk into smaller segmented sections.

To complete the discussion of the DPB, recall that several DPH's can address the same DPB if their drive characteristics are identical. Further, the DPB can be dynamically changed when a new drive is addressed by simply changing the pointer in the DPH since the BDOS copies the DPB values to a local area whenever the SELDSK function is invoked.

Returning back to the DPH for a particular drive, note that the two address values CSV and ALV remain. Both addresses reference an area of uninitialized memory following the BIOS. The areas must be unique for each drive, and the size of each area is determined by the values in the DPB.

The size of the area addressed by CSV is CKS bytes, which is sufficient to hold the directory check information for this particular drive. If CKS = (DRM+1)/4, then you must reserve (DRM+1)/4 bytes for directory check use. If CKS = 0, then no storage is reserved.

(All Information Contained Herein is Proprietary to Digital Research.)

The size of the area addressed by ALV is determined by the maximum number of data blocks allowed for this particular disk, and is computed as (DSM/8)+1.

The CBIOS shown in Appendix C demonstrates an instance of these tables for standard 8" single density drives. It may be useful to examine this program, and compare the tabular values with the definitions given above.

11. THE DISKDEF MACRO LIBRARY.

A macro library is shown in Appendix F, called DISKDEF, which greatly simplifies the table construction process. You must have access to the MAC macro assembler, of course, to use the DISKDEF facility, while the macro library is included with all CP/M 2.0 distribution disks.

A BIOS disk definition consists of the following sequence of macro statements:

```
MACLIB    DISKDEF
......
DISKS     n
DISKDEF   0,...
DISKDEF   1,...
......
DISKDEF   n-1
......
ENDEF
```

where the MACLIB statement loads the DISKDEF.LIB file (on the same disk as your BIOS) into MAC's internal tables. The DISKS macro call follows, which specifies the number of drives to be configured with your system, where n is an integer in the range 1 to 16. A series of DISKDEF macro calls then follow which define the characteristics of each logical disk, 0 through n-1 (corresponding to logical drives A through P). Note that the DISKS and DISKDEF macros generate the in-line fixed data tables described in the previous section, and thus must be placed in a non-executable portion of your BIOS, typically directly following the BIOS jump vector.

The remaining portion of your BIOS is defined following the DISKDEF macros, with the ENDEF macro call immediately preceding the END statement. The ENDEF (End of Diskdef) macro generates the necessary uninitialized RAM areas which are located in memory above your BIOS.

The form of the DISKDEF macro call is

        DISKDEF dn,fsc,lsc,[skf],bls,dks,dir,cks,ofs,[0]

where

        dn   is the logical disk number, 0 to n-1
        fsc   is the first physical sector number (0 or 1)
        lsc   is the last sector number
        skf   is the optional sector skew factor
        bls   is the data allocation block size
        dir   is the number of directory entries
        cks   is the number of "checked" directory entries
        ofs   is the track offset to logical track 00
        [0]   is an optional 1.4 compatibility flag

The value "dn" is the drive number being defined with this DISKDEF

macro invocation. The "fsc" parameter accounts for differing sector numbering systems, and is usually 0 or 1. The "lsc" is the last numbered sector on a track. When present, the "skf" parameter defines the sector skew factor which is used to create a sector translation table according to the skew. If the number of sectors is less than 256, a single-byte table is created, otherwise each translation table element occupies two bytes. No translation table is created if the skf parameter is omitted (or equal to 0). The "bls" parameter specifies the number of bytes allocated to each data block, and takes on the values 1024, 2048, 4096, 8192, or 16384. Generally, performance increases with larger data block sizes since there are fewer directory references and logically connected data records are physically close on the disk. Further, each directory entry addresses more data and the BIOS-resident ram space is reduced. The "dks" specifies the total disk size in "bls" units. That is, if the bls = 2048 and dks = 1000, then the total disk capacity is 2,048,000 bytes. If dks is greater than 255, then the block size parameter bls must be greater than 1024. The value of "dir" is the total number of directory entries which may exceed 255, if desired. The "cks" parameter determines the number of directory items to check on each directory scan, and is used internally to detect changed disks during system operation, where an intervening cold or warm start has not occurred (when this situation is detected, CP/M automatically marks the disk read/only so that data is not subsequently destroyed). As stated in the previous section, the value of cks = dir when the media is easily changed, as is the case with a floppy disk subsystem. If the disk is permanently mounted, then the value of cks is typically 0, since the probability of changing disks without a restart is quite low. The "ofs" value determines the number of tracks to skip when this particular drive is addressed, which can be used to reserve additional operating system space or to simulate several logical drives on a single large capacity physical drive. Finally, the [0] parameter is included when file compatibility is required with versions of 1.4 which have been modified for higher density disks. This parameter ensures that only 16K is allocated for each directory record, as was the case for previous versions. Normally, this parameter is not included.

For convenience and economy of table space, the special form

                    DISKDEF   i,j

gives disk i the same characteristics as a previously defined drive j. A standard four-drive single density system, which is compatible with version 1.4, is defined using the following macro invocations:

```
        DISKS       4
        DISKDEF     0,1,26,6,1024,243,64,64,2
        DISKDEF     1,0
        DISKDEF     2,0
        DISKDEF     3,0
        ....
        ENDEF
```

with all disks having the same parameter values of 26 sectors per track (numbered 1 through 26), with 6 sectors skipped between each access, 1024 bytes per data block, 243 data blocks for a total of 243k byte disk capacity, 64 checked directory entries, and two operating system tracks.

     The DISKS macro generates n Disk Parameter Headers (DPH's), starting at the DPH table address DPBASE generated by the macro. Each disk header block contains sixteen bytes, as described above, and correspond one-for-one to each of the defined drives. In the four drive standard system, for example, the DISKS macro generates a table of the form:

```
    DPBASE    EQU   $
    DPE0:     DW    XLT0,0000H,0000H,0000H,DIRBUF,DPB0,CSV0,ALV0
    DPE1:     DW    XLT0,0000H,0000H,0000H,DIRBUF,DPB0,CSV1,ALV1
    DPE2:     DW    XLT0,0000H,0000H,0000H,DIRBUF,DPB0,CSV2,ALV2
    DPE3:     DW    XLT0,0000H,0000H,0000H,DIRBUF,DPB0,CSV3,ALV3
```

where the DPH labels are included for reference purposes to show the beginning table addresses for each drive 0 through 3. The values contained within the disk parameter header are described in detail in the previous section. The check and allocation vector addresses are generated by the ENDEF macro in the ram area following the BIOS code and tables.

     Note that if the "skf" (skew factor) parameter is omitted (or equal to 0), the translation table is omitted, and a 0000H value is inserted in the XLT position of the disk parameter header for the disk. In a subsequent call to perform the logical to physical translation, SECTRAN receives a translation table address of DE = 0000H, and simply returns the original logical sector from BC in the HL register pair. A translate table is constructed when the skf parameter is present, and the (non-zero) table address is placed into the corresponding DPH's. The table shown below, for example, is constructed when the standard skew factor skf = 6 is specified in the DISKDEF macro call:

```
    XLT0:     DB    1,7,13,19,25,5,11,17,23,3,9,15,21
              DB    2,8,14,20,26,6,12,18,24,4,10,16,22
```

     Following the ENDEF macro call, a number of uninitialized data areas are defined. These data areas need not be a part of the BIOS which is loaded upon cold start, but must be available between the BIOS and the end of memory. The size of the uninitialized RAM area is determined by EQU statements generated by the ENDEF macro. For a standard four-drive system, the ENDEF macro might produce

```
4C72 =          BEGDAT EQU $
                (data areas)
4DB0 =          ENDDAT EQU $
013C =          DATSIZ EQU $-BEGDAT
```

which indicates that uninitialized RAM begins at location 4C72H, ends at 4DB0H-1, and occupies 013CH bytes. You must ensure that these addresses are free for use after the system is loaded.

After modification, you can use the STAT program to check your drive characteristics, since STAT uses the disk parameter block to decode the drive information. The STAT command form

<p align="center">STAT d:DSK:</p>

decodes the disk parameter block for drive d (d=A,...,P) and displays the values shown below:

```
        r: 128 Byte Record Capacity
        k: Kilobyte Drive  Capacity
        d: 32  Byte Directory Entries
        c: Checked  Directory Entries
        e: Records/ Extent
        b: Records/ Block
        s: Sectors/ Track
        t: Reserved Tracks
```

Three examples of DISKDEF macro invocations are shown below with corresponding STAT parameter values (the last produces a full 8-megabyte system).

```
        DISKDEF 0,1,58,,2048,256,128,128,2
  r=4096, k=512, d=128, c=128, e=256, b=16, s=58, t=2

        DISKDEF 0,1,58,,2048,1024,300,0,2
  r=16384, k=2048, d=300, c=0, e=128, b=16, s=58, t=2

        DISKDEF 0,1,58,,16384,512,128,128,2
  r=65536, k=8192, d=128, c=128, e=1024, b=128, s=58, t=2
```

12. SECTOR BLOCKING AND DEBLOCKING.

Upon each call to the BIOS WRITE entry point, the CP/M BDOS includes information which allows effective sector blocking and deblocking where the host disk subsystem has a sector size which is a multiple of the basic 128-byte unit. The purpose here is to present a general-purpose algorithm which can be included within your BIOS which uses the BDOS information to perform the operations automatically.

Upon each call to WRITE, the BDOS provides the following information in register C:

0	=	normal sector write
1	=	write to directory sector
2	=	write to the first sector
		of a new data block

Condition 0 occurs whenever the next write operation is into a previously written area, such as a random mode record update, when the write is to other than the first sector of an unallocated block, or when the write is not into the directory area. Condition 1 occurs when a write into the directory area is performed. Condition 2 occurs when the first record (only) of a newly allocated data block is written. In most cases, application programs read or write multiple 128 byte sectors in sequence, and thus there is little overhead involved in either operation when blocking and deblocking records since pre-read operations can be avoided when writing records.

Appendix G lists the blocking and deblocking algorithms in skeletal form (this file is included on your CP/M disk). Generally, the algorithms map all CP/M sector read operations onto the host disk through an intermediate buffer which is the size of the host disk sector. Throughout the program, values and variables which relate to the CP/M sector involved in a seek operation are prefixed by "sek," while those related to the host disk system are prefixed by "hst." The equate statements beginning on line 29 of Appendix G define the mapping between CP/M and the host system, and must be changed if other than the sample host system is involved.

The entry points BOOT and WBOOT must contain the initialization code starting on line 57, while the SELDSK entry point must be augmented by the code starting on line 65. Note that although the SELDSK entry point computes and returns the Disk Parameter Header address, it does not physically selected the host disk at this point (it is selected later at READHST or WRITEHST). Further, SETTRK, SETTRK, and SETDMA simply store the values, but do not take any other action at this point. SECTRAN performs a trivial trivial function of returning the physical sector number.

The principal entry points are READ and WRITE, starting on lines 110 and 125, respectively. These subroutines take the place of your previous READ and WRITE operations.

The actual physical read or write takes place at either WRITEHST or READHST, where all values have been prepared: hstdsk is the host

disk number, hsttrk is the host track number, and hstsec is the host sector number (which may require translation to a physical sector number). You must insert code at this point which performs the full host sector read or write into, or out of, the buffer at hstbuf of length hstsiz. All other mapping functions are performed by the algorithms.

This particular algorithm was tested using an 80 megabyte hard disk unit which was originally configured for 128 byte sectors, producing approximately 35 megabytes of formatted storage. When configured for 512 byte host sectors, usable storage increased to 57 megabytes, with a corresponding 400% improvement in overall response. In this situation, there is no apparent overhead involved in deblocking sectors, with the advantage that user programs still maintain the (less memory consuming) 128-byte sectors. This is primarily due, of course, to the information provided by the BDOS which eliminates the necessity for pre-read operations to take place.

; this is a sample cold start loader which, when modified
; resides on track 00, sector 01 (the first sector on the
; diskette).  we assume that the controller has loaded
; this sector into memory upon system start-up (this pro-
; gram can be keyed-in, or can exist in read/only memory
; beyond the address space of the cp/m version you are
; running).  the cold start loader brings the cp/m system
; into memory at "loadp" (3400h + "bias").  in a 20k
; memory system, the value of "bias" is 0000h, with large
; values for increased memory sizes (see section 2). afte
; loading the cp/m system, the clod start loader branches
; to the "boot" entry point of the bios, which begins at
; "bios" + "bias."  the cold start loader is not used un-
; til the system is powered up again, as long as the bios
; is not overwritten.  the origin is assumed at 0000h, an
; must be changed if the controller brings the cold start
; loader into another area, or if a read/only memory area
; is used.
